IS POINTING THE ROOT OF THE FOOT?
GROUNDING THE «PROSODIC WORD» AS A POINTING WORD

Recently in the Vocalize-to-Localize framework (a functional stance just started in the Interaction Studies 2004-2005 issues we edited, Abry et al., 2004), we addressed the unification of two grounding attempts concerning the syllable and the foot in language ontogeny. Can the movement time of the pointing strokes of a child be predicted from her babbling rhythm? The answer for 6 babies (6-18 months) was a 2:1 pointing-to-syllable ratio. Implications for the grounding of the first words within this Pointing Frame will be examined. More tentatively we will suggest that babbling for protophonology together with pointing for protosyntax pave the way to language.

1. Introduction

While the main scientific endeavour is fission, say first break already known units, as in physics typically, the afterthought of formal constructions is to restart from primitives, e.g. building blocks. This is the foundational Chomsky & Schützenberger's free monoid for computational linguistics, then Move and/or Merge in the Minimalist Programme (MP). In physiological behavior the degrees-of-freedom problem is rather seen developmentally as a problem of breaking early given coordinations (e.g. thumb-sucking in utero, Babkin’s reflex, etc.) in order to elaborate new couplings for new skills (hand-to-mouth feeding... piano playing).

2. Emergence as mergence: Sign+Sign=>Sign and Foot+Foot=>Foot

Regarding the emergence of phonology, some students like Lindblom and ourselves have considered that features, particles, primes, etc., are just by-products of other mechanisms (for a recent tentative reconciliation with the use
of features within our *Perception-for-Action-Control-Theory*, see Schwartz, Boë & Abry, 2007). But what are the unit of the system you start from? The number of segments? The possible onsets and offsets of syllables...? In computational evolutionary phonology, the issue is still between a holistic-formulaic starting point, or a yet undefined layman word unit. This in spite of our linguistic state-of-the art, since «we still do not have strict definitions of even the most basic units, such as segment, syllable, morpheme, and word», as complained by Joan Bybee (2003, p. 2).

Now instead of fission, can fusion help? In other words can the compositional making of larger units from smaller bricks, be replaced by the blending of already more or less large units, typically two into one unit of the same level (an idea taken earlier in the *categorial grammar* formalism, still compatible with MP)? Which of course leaves open the evolutionary issue about where they could come from.

Let us take an example from a still-on-the-making phonology. In Sign Language, where no stable consensus does exist about phonological units, can one use semantic blending and morphological fusion to evidence these components? In ASL, *MIND+DROP*=>*FAINT* (we are indebted to Wendy Sandler for this videoclip example). If *Sign+Sign*=>*Sign* is semantic blending (*snowman*), what are the corresponding phonological units? Is there a sign-language specific «syllable conspiracy», as Sandler claims: *Syll+Syll*=>*Syll*? Or a more common foot isochrony *Foot+Foot*=>*Foot*? Like one-foot *music, musical, musically? Snowman is obviously shorter than snow+man duration. In fact, once measured, the downstroke phase of *FAINT* (which starts from the head for *MIND*, with the finger point erased) is just a videoframe longer than the one for *DROP* (starting lower from the waist). Which is a strong cue of isochrony control for compression in one unit (chunk, template, etc.).

Is that just emergence-supervenience of units due to informational constraints, just language-use, the war of attrition on constructions as form-meaning pairings, in cognitive construction grammars? Said otherwise: data compression for *sparse coding*? Are there no macroscopic units corresponding to universal *control* units, macroscopic primitives for making morphogenetic «language bubbles», not acquired simply by perceptuo-motor statistical pattern-finding? Are there phonologically universal babble-syllable constraints in speech acquisition, and more, signs and words in both speech and sign language (even if syllables could be not ubiquitous in both media)? In other words, when in evo-development do you get a tuner for tuning? Who could attune what, along language attunement-imitation, without a specific what-tuner to capture the preferred radiostation among the buzzy broadcasting landscape of speakers?
3. The syllable, then the point: whence the word?

Recently in the Vocalize-to-Localize framework (a functional stance just started in the Interaction Studies 2004-2005 issues we edited, see Abry, Vilain & Schwartz, 2004), we addressed the unification of two grounding attempts concerning the syllable and the foot in language ontogeny. Both units are highly disputed among phonologists and psycholinguists. But the proposal of a root for proto-syllables in canonical babbling can now be neurally evaluated on the basis of a motor control platform: MacNeilage's Frame/Content theory starting from the control of the mandible as the carrier articulator. We proposed the same ground of evaluation for the foot as the basic control unit for the phonology of the proto-word. We predicted that, if we would measure the babbling rhythm of a baby from the burst of canonical babbling around 6-7 months, we could calculate the range of duration of her pointing arm-strokes, from 9 months upwards. Tested on 6 French children in a longitudinal study, each fortnight between 6 and 18 months, this «astonishing» hypothesis was globally successful (Ducey, 2007), with a mean 2.18 pointing/babbling ratio. Moreover each child had at her disposal in her repertoire a sufficiently long point to cover a disyllabic utterance.

Like for linguistic demonstratives, the semantics, pragmatics, and even the syntax of pointing have all deserved valuable attention and brought out results in related fields. And Sign Language phonology too, which meets ubiquitously pointing. But nothing was said about the proper phonological integrative links of the pointing gesture with speech phonological units, smaller or larger than the point, like the syllable, the foot, and the so-called «prosodic word».

We can now consider that the phonology of the point with the arm-index could give for free the template of the ubiquitous one/two-syllable word foot (instead of an arbitrary FOOTBIN in Optimality Theory, where a one-syllable/moraic foot is considered as «degenerated» or «subminimal»). Grounding the phonology of the point motorically, in the neural arm-index control, gives thus for free the template of the two-syllable word as a coordination of the hand and the mouth in language semiotics and phonetics. This result offers in addition considerable insights in line with the parallel development of syntax use of THat-demonstratives and WHat-interrogatives through the grammatization process in the world's languages (Diesel, 1999). It is in favor of an early demonstrative site, later attuned to language specific morphonology: see English (the) house vs. Swedish huset, French la maison vs. Rumanian domul; and even more elaborated compounding, with what could be
tagged «double filled sites»: French cette maison-ci vs. Swedish det här huset, or Afrikaans hierdie huis, etc.

This is just one of the issues, the developmental framework reminded below (Fig.1), allowed us to address up to now, in between the Vocalize-to-Localize (2003) seminar and the 2007 VOCOID (VOcalization, COMmunication, Imitation, and Deixis, in infant and adult human and non-human primates), both international meetings we organized in Grenoble.

4. Beyond the presented Framework (Fig.1)

Beyond reinforcing the very general claim that «pointing is the royal road to language for babies» (as recalled by the late George Butterworth in Kita, Pointing, 2003), we can add to our prediction of pointing stroke duration distributions from individual babbling rhythm distributions another replicated prediction: namely the prediction that two-word utterance emergence can be calculated from the beginning of the coproduction of a word together with a non redundant pointing (a result found in Susan Goldin-Meadow's group, and replicated with Jana Iverson in Iverson & Goldin-Meadow, 2005). Since this is not a pure slot-grammar story (POINT+Word gives Word+Word, but the POINT is still there in the predicate-argument structure), the rationale behind this development beyond the first year word, remains still a lot mysterious (personal conversation with Susan Goldin-Meadow and Elena Lieven).

Finally we will add work in progress on two possible neural circuits found in adults, which could be relevant for language acquisition of the word-foot metric unit, namely the one we dubbed the THAT-PATH, for pointing with the eye, the arm and the voice (Loevenbruck et al., 2005, 2007). And ultimately the verbal working memory network, we dubbed the STABIL-LOOP (Abry, Vilain & Schwartz, 2004), for stabilizing the linguistic word forms (Abry et al., 2003, Sato et al., 2004, 2006). Working memory was already proposed by Francisco Aboitiz and Ricardo Garcia (1997) as a masterpiece in the primate evolution toward language, but with little concern about language (universal) preferred forms before matching for recall. We will insist here on the fact that, in our view, this STABIL-LOOP system can stabilize both word order (basic syntax and compounds) and word form structure (morphonology).

5. Summary

Beyond the fission/fusion metaphors, several of these empirical findings from ontogeny could help in building an evo-devo story of language with caveats:
(i) Syllables are definitely not built from segments; but segments are a late by-product of new degrees of freedom, making the carried lip and tongue articulator more and more independent from the carrier jaw (rhythm control).

(ii) Words are neither built from syllables; but chunked from the babbling flow, in the pointing frame (discrete stroke control).

(iii) Syntax does not emerge with 2-word utterances; but syntactic demonstrative (argumentative-referencing) pointing is there from the first word; and still there when 2 words appear, depending on the preceding date of emergence of the skill of pointing to the argument while predicating about a different referent from the pointed one (e.g. saying «Daddy», while pointing to his shoes... be Daddy's feet inside or not, from a strictly logical point of view).
babbling cycles of a child, one can predict the range of durations of her pointing strokes: in-between 2-3 syllables in a point, that is a universal trend for the word... point.
